## ABSTRACT

We use very long baseline interferometry to measure the proper motions of three black hole X-ray binaries (BHXBs). Using these results together with data from the literature and *Gaia* DR2 to collate the best available constraints on proper motion, parallax, distance, and systemic radial velocity of 16 BHXBs, we determined their three-dimensional Galactocentric orbits. We extended this analysis to estimate the probability distribution for the potential kick velocity (PKV) a BHXB system could have received on formation. Constraining the kicks imparted to BHXBs provides insight into the birth mechanism of black holes (BHs). Kicks also have a significant effect on BH–BH merger rates, merger sites, and binary evolution, and can be responsible for spin–orbit misalignment in BH binary systems. 75 per cent of our systems have potential kicks  $> 70 \text{ km s}^{-1}$ . This suggests that strong kicks and hence spin–orbit misalignment might be common among BHXBs, in agreement with the observed quasi-periodic X-ray variability in their power density spectra. We used a Bayesian hierarchical methodology to analyse the PKV distribution of the BHXB population, and suggest that a unimodal Gaussian model with a mean of  $107 \pm 16 \text{ km s}^{-1}$  is a statistically favourable fit. Such relatively high PKVs would also reduce the number of BHs likely to be retained in globular clusters. We found no significant correlation between the BH mass and PKV, suggesting a lack of correlation between BH mass and the BH birth mechanism. Our PYTHON code allows the estimation of the PKV for any system with sufficient observational constraints.

**Key words:** astrometry – parallaxes – proper motions – stars: kinematics and dynamics – X-rays: binaries.

## 1 INTRODUCTION

Theoretical models suggest the formation of a stellar-mass black hole (BH) could take place either by (a) direct collapse, whereby the massive progenitor star collapses directly into a BH with almost no

\* E-mail: [pikky.atri@postgrad.curtin.edu.au](mailto:pikky.atri@postgrad.curtin.edu.au) (PA); [Jones@curtin.edu.au](mailto:Jones@curtin.edu.au) (JCAM-J)

mass ejection (e.g. Reynolds, Fraser & Gilmore 2015; Adams et al. 2017), or (b) delayed formation in a supernova (SN), wherein matter ejected during the SN falls back on to the proto-neutron star, creating a BH (e.g. Gourgoulhon 1991; Brandt, Podsiadlowski & Sigurdsson 1995; Woosley & Weaver 1995). The theoretical mass distribution derived by Fryer & Kalogera (2001) suggests that beyond a critical progenitor mass of  $40 M_{\odot}$  (assuming no mass-loss through winds), BHs form via direct collapse and an SN explosion does not occur. However, more recent work suggests that the formation of BHs by direct collapse (implosion) has a wider progenitor mass range, interspersed by narrow pockets of progenitor masses that undergo an SN explosion to become a BH (Sukhbold et al. 2016). Obtaining observational evidence about how a BH was born for a range of BH masses could help in understanding the relation between the BH birth model and BH mass.

Isolated stellar-mass BHs are difficult to observe. Thus, black hole X-ray binaries (BHXBs) can be used as probes to understand the birth mechanism of BHs in binary systems. If a BH in a binary system is formed due to an SN explosion, the sudden mass-loss from the binary system will change the centre of mass of the remnant binary system. Even if the SN explosion is symmetric in the frame of reference of the progenitor, the change in the centre of mass of the binary system will give the remnant binary system a recoil kick. This kick is referred to as the Blaauw kick (Blaauw 1961). The ejected mass in the SN needs to be less than half the total mass of the system in order for the remnant binary system to stay bound. This corresponds to a maximum recoil kick of a few tens of  $\text{km s}^{-1}$ , depending on the binary mass, progenitor velocity, orbital period, and ejected mass of the system (Nelemans, Tauris & van den Heuvel 1999).

BHXBs that have peculiar velocities higher than the Blaauw kick, which the system could have acquired due to symmetric mass-loss, need some other mechanism to explain the high velocities. The space velocity distribution of pulsars was shown to have a mean of  $450 \text{ km s}^{-1}$  with a high-velocity tail (Lyne & Lorimer 1994). Verbunt, Igoshev & Cator (2017, V17 hereafter) used accurately measured pulsar proper motions and parallaxes applying a Bayesian method to estimate distances from parallaxes. They found that the velocity distribution was wider than can be fit by a single Maxwellian, and has two prominent peaks, at  $120$  and  $540 \text{ km s}^{-1}$ . The high-velocity kicks (Lyne & Lorimer 1994) have been attributed to a variety of mechanisms during the SN explosion. Even if the matter ejected in the SN explosion is symmetric, the anisotropy in the neutrino emission caused by strong magnetic fields could accelerate pulsars to high velocities (Chugai 1984; Sagert & Schaffner-Bielich 2008). Other mechanisms that could be responsible for high kick velocities include supersonic jet generation during a stellar core collapse (Khokhlov et al. 1999), or an intrinsically asymmetric explosion due to hydrodynamic perturbations in the SN core (Janka 2017).

Since these kick mechanisms occur prior to the fallback of matter on the proto-neutron star and consequent BH formation (Gourgoulhon & Haensel 1993), it is plausible that BHs formed by the fallback process should also receive such strong natal kicks. It is expected that the velocity kicks BHs receive will be smaller than NS velocity kicks because BHs are more massive than NSs. On the other hand, fallback of slower moving ejecta from the SN explosion could accelerate the BH (Janka 2013). This would imply that BHs born in an SN explosion could also get large kicks at birth. BHs born by direct collapse are expected to receive kicks lower than those obtained due to birth in SN explosion (Belczynski, Bulik & Kalogera 2002). Hence, natal kick measurements provide

effective probes to differentiate between the SN and direct collapse birth pathways.

In the absence of direct kick measurements, the height of known BHXBs above the Galactic plane has been used as a proxy (e.g. White & van Paradijs 1996; Jonker & Nelemans 2004) given that the majority of the progenitor systems are closely confined to the plane. Various natal kick distributions were used to simulate BHXB populations and it was found that natal kicks are essential to explain the large displacement of a number of systems from the Galactic plane (Repetto, Davies & Sigurdsson 2012; Repetto, Igoshev & Nelemans 2017). However, Mandel (2016) showed that for extreme assumptions (i.e. all systems are currently at maximum  $z$ ) BH kicks of  $> 100 \text{ km s}^{-1}$  are not required to explain the observed distribution of heights ( $|z|$ ) above the Galactic plane. Measuring space velocities and positions of BHXBs provides extra information that helps to relate the  $|z|$  distribution to the natal kicks received by the BHs and in turn resolve this discrepancy.

### 1.1 BH–BH mergers

With the discovery of BH mergers from gravitational wave (GW) events (Abbott et al. 2016a), we are achieving new insights into the stellar-mass BH mass distribution (Abbott et al. 2016b; The LIGO Scientific Collaboration & The Virgo Collaboration 2018) and stellar-mass BH formation. According to theoretical models, BH–BH binaries are formed due to dynamical interactions in high-density clusters (Fabian, Pringle & Rees 1975; Goodman & Hut 1993; Sigurdsson & Hernquist 1993; Sigurdsson & Phinney 1993; Benacquista & Downing 2013) e.g. in globular clusters (GCs) (Rodriguez et al. 2016) and Galactic nuclear clusters. They can also be formed due to hierarchical three-body interactions (Antonini, Gieles & Gualandris 2019), or in the Galactic field, which hosts the astrophysical stellar binaries that evolve into BH–BH binaries (Belczynski et al. 2002; Postnov & Yungelson 2014).

Strong natal kicks could lead to the BHs being kicked out of a GC before they could become BH–BH binaries, or result in unbinding the binary system. This would hinder BH–BH binary formation and in turn reduce the rate of BH–BH mergers. Natal kicks are thus a deciding factor in the rate of BH–BH mergers (Wysocki et al. 2018). Natal kicks are also considered to be responsible for spreading the BH binary merger sites further away from the host halo (Kelley et al. 2010). While it is currently poorly constrained, the BH natal kick distribution is a key parameter in  $N$ -body simulations of GCs, used to estimate the number of BHs that are retained or ejected upon formation and due to subsequent dynamical interactions (e.g. Strader et al. 2012; Heggie & Giersz 2014; Giesler, Clausen & Ott 2018). Thus, the natal kick distribution has important implications for the likelihood of finding BH–BH binaries, and also BHXBs in GCs.

### 1.2 Existing natal kick constraints

While we know of  $\sim 60$  strong candidate BH systems (Corral-Santana et al. 2016; Tetarenko et al. 2016a), only seven BHXB candidates have been analysed to determine if they were born in an SN with substantial mass ejection, rather than a direct collapse. System parameters like component masses, orbital period, donor effective temperature, and the three-dimensional motion of BHXBs need to be well constrained if the complete evolutionary history of these BHXB systems is to be mapped. The Galactocentric orbits of such systems with well-known parameters could be integrated back to a reasonable range of their ages, thus the velocity of the

system immediately after the BH birth could be determined. Such an analysis has been conducted for three systems, namely, XTE J1118+40 (Willems et al. 2005), GRO J1655–40 (Fragos et al. 2009), and Cyg X–1 (Wong et al. 2012).

The post SN peculiar velocity of XTE J1118+40 along with the assumption that the system was born in the Galactic plane indicated that the system received an asymmetric natal kick (Fragos et al. 2009). The high peculiar velocity could also mean that the system was a GC escapee (Mirabel et al. 2001; Gualandris et al. 2005), in which case the assumption that it was born in the Galactic plane would not hold. It was suggested that GRO J1655–40 was born in an SN and received a kick when the BH was formed (Brandt et al. 1995; Mirabel et al. 2002; Willems et al. 2005), though the strength of the kick did not require an asymmetric explosion (Nelemans et al. 1999). Cyg X–1 was found to have received a small kick velocity at birth (Mirabel & Rodrigues 2003; Wong et al. 2012).

Only the peculiar velocities were used to infer whether the kicks BHXBs systems received were high enough to suggest an SN origin for the other four systems (e.g. Mirabel et al. 2001; Mirabel & Rodrigues 2003; Dhawan et al. 2007; Miller-Jones et al. 2009a; Gandhi et al. 2019). This has been done by measuring the proper motion of the BHXBs, and combining them with the line-of-sight velocities and the distances to the systems to measure the velocities of the systems with respect to the local standard of rest (i.e. the peculiar velocity). This gives the full three-dimensional motion of the BHXBs, which enables us to trace the Galactocentric orbits through the Galactic potential. A low peculiar velocity was measured for GRS 1915+105 (Dhawan et al. 2007; Reid et al. 2014), which suggested that the system could have been born by direct collapse. The inferred peculiar velocities of V404 Cyg (Miller-Jones et al. 2009a), VLA J2130+12 (Tetarenko et al. 2016b), and MAXI J1836–194 (Russell et al. 2015) were more consistent with a symmetric SN explosion. This is a small sample size, with estimations of the minimum natal kick having been made using different methods. Thus in order to draw statistically robust conclusions about the natal kick distribution of BHs, we need to increase this sample size and adopt a more systematic approach. In this paper we increase the sample size of estimated kick velocities of BHXBs to 16, by combining measured proper motions, systemic radial velocities, and distances to these systems.

### 1.3 Peculiar velocity and potential kick velocity

Using the current peculiar velocity of a system to infer the strength of the kick the system might have received at birth has a few limitations. Peculiar velocity is the current three-dimensional velocity of a system relative to the local standard of rest and thus changes based on the epoch of observation. Also, using peculiar velocity relative to that expected from Galactic rotation as an indicator of natal kick velocity could be misleading for sources that are far away from the Galactic plane. Our analysis tries to minimize these shortcomings by instead using the peculiar velocity of the system when it crosses the Galactic plane, which we refer to as the potential kick velocity (PKV).

In this paper we have combined the capabilities of VLBI and *Gaia* to get observationally constrained BH PKV probability distributions for 16 systems. In Section 2 we identify the BHXB sample we used for our analysis and mention the observational biases this sample suffers from. In Section 3 we discuss the data acquisition and reduction procedures followed to measure proper motions for GX 339–4, GRS 1716–249, and *Swift* J1753.5–0127, which is followed by Section 4 where we present the proper motion

measurements of the above-mentioned three systems. In Section 5 we go through the details of distance estimation from parallax measurements using a Milky Way prior (Section 5.1) and the systemic radial velocity estimates for the systems that did not have measured systemic radial velocity in literature (Section 5.2). Section 6 explains the Monte Carlo (MC) code we developed to determine the PKV probability distributions and present the PKV distributions for all 16 sources. Section 7 discusses the implications of these results.

## 2 DATA

### 2.1 BHXB sample

To determine the three-dimensional motion of BHXBs, we need to combine the proper motion, systemic radial velocity, and distances to these systems. The literature already contains estimates of the current peculiar velocity for seven of our systems, XTE J1118+480 (Mirabel et al. 2001), GRO 1655–40 (Mirabel et al. 2002), Cyg X–1 (Mirabel & Rodrigues 2003), GRS 1915+105 (Dhawan et al. 2007), V404 Cyg (Miller-Jones et al. 2009a), MAXI J1836–194 (Russell et al. 2015), and VLA J2130+12 (Tetarenko et al. 2016b). *Gaia* in its second data release (DR2) measured the proper motions of 11 BHXBs, three of which were improvements on previous measurements (Cyg X–1, GRO J1655–40, and XTE J1118+480; Mirabel et al. 2001, 2002; Mirabel & Rodrigues 2003). Gandhi et al. (2019) estimated the current peculiar velocities for BHXBs for which *Gaia* DR2 (Gaia Collaboration 2018) measured proper motions and parallaxes. We use these proper motion and parallax measurements along with the very long baseline interferometry (VLBI; Shapiro et al. 1979) measurements present in the literature (based on whichever was more precise) for our analysis.

Typical BHXBs have proper motions of a few  $\text{mas yr}^{-1}$ , which can be measured by the *Gaia* satellite (Lindgren et al. 2016) or with VLBI. The quiescent optical brightness of BHXBs is usually near to or below the limiting magnitude of the *Gaia* satellite, and they only get bright enough for high-precision astrometry with *Gaia* when they are in outburst. This makes proper motion measurements challenging for many of these sources. *Gaia* would also not be able to detect BHXBs towards the Galactic bulge due to high extinction. Thus, triggered VLBI observations when a BHXB goes into an outburst can probe systems not accessible to *Gaia*. We used VLBI to measure the proper motions of three new sources: GX 339–4, *Swift* J1753.5–0127, and GRS 1716–249.

### 2.2 Sample biases

Our sample set of 16 BHXB suffers from certain observational biases. There are a few systems in our sample that are not dynamically confirmed BHs but are BHXB candidates (see Tetarenko et al. 2016b for a summary of all BHXB candidates). Notably, the nature of VLA J2130+12 that is a BHXB detected in quiescence (Kirsten et al. 2014) is still under debate (Tetarenko et al. 2016a). We include Cyg X–1 in our analysis even though it is a younger, high-mass X-ray binary (HMXB) with a potentially more massive donor star than that of a typical low-mass X-ray binary. This is because it has well-constrained parameters and thus is a good test source.

We note that almost all BHXBs in our sample have been in outburst at some point, except VLA J2130+12. During outbursts typical BHXBs reach X-ray peak luminosities of  $>10^{37-39} \text{ erg s}^{-1}$ . Thus the sample is devoid of any very faint X-ray transients

(Wijnands et al. 2006), which have peak luminosities of  $10^{36-37}$  erg s $^{-1}$  (Heise 1999). We are biased against observing BHs that received kicks strong enough to unbind the binary system, as we can only observe BHs in X-ray binaries. We may also be observationally biased against distant, low-kick systems as they will be very close to the Galactic plane and therefore will be highly extincted.

### 3 VLBI OBSERVATIONS AND DATA REDUCTION

To measure the proper motions of GX 339–4, GRS 1716–249, and *Swift* J1753.5–0127, we used the Very Long Baseline Array (VLBA), the European VLBI Network (EVN), and the Australian Long Baseline Array (LBA). The observational set-ups are summarized in Table 1. The hard X-ray spectral state of BHXBs is associated with the rising and decaying phases of the outbursts (Belloni & Motta 2016). The radio jets during the hard spectral state are compact, steady, and are causally connected to the BH (Fender, Homan & Belloni 2009). Thus the hard state is an ideal phase during the outburst to conduct astrometry. High-precision astrometry can be conducted even if the target image is resolved (Reid et al. 2011). The observations need to be separated in time by at least a couple of months to provide a sufficient time baseline for a proper motion measurement. Thus, depending on how long the source stays in a hard state, we need to observe it over one or multiple outbursts.

The data were correlated using the DIFX software correlator (Deller et al. 2011) and reduced using the Astronomical Image Processing System (AIPS 31DEC17; Greisen 2003). Observations of bright fringe finder sources were used to correct for non-zero instrumental delays and rates. The observations of the target were bracketed by shorter observations of a phase reference calibrator, located as close to the target as possible (preferably  $<2^\circ$ ; Pradel, Charlot & Lestrade 2006). The details of the calibrators used for each target are summarized in Table 2.

For observations made at frequencies higher than 5 GHz using the VLBA, numerous widely separated calibrators were observed in quick succession (geodetic blocks) for  $\sim 30$  min at the start and end of each observing run. Geodetic blocks help in determining any error in the estimated zenith tropospheric delay and thus improve astrometric accuracy. The multiband delays were corrected using standard AIPS procedures (AIPS Memo 110). The overheads associated with observing a geodetic block with the LBA and the EVN were high due to the large dish sizes and consequent slow slew rates of the dishes involved, and hence we did not observe geodetic blocks with the LBA and the EVN. The stations included in the LBA and the EVN are not solely for the purpose of VLBI, and so have infrequent formal VLBI observing sessions. For any transients that have to be observed out of the standard observing sessions, the source is observed with whatever stations are available. This gives varying sensitivity and resolution from epoch to epoch.

#### 3.1 GX 339–4

GX 339–4 is a low-mass black hole X-ray binary (LMXB), which was first detected in 1973 (Markert et al. 1973). This system goes into frequent outbursts, with 20 outbursts since its detection (Tetarenko et al. 2016a). Hence, astrometry over multiple outbursts is possible. The optical emission from the accretion disc of the system even during the low-luminosity quiescent phase makes the detection of the donor star difficult (Shahbaz, Fender & Charles 2001). Recently, NIR spectra of GX 339–4 were obtained using the

VLT/X-Shooter during quiescence, which led to a systemic radial velocity measurement of  $\gamma = 26 \pm 2$  km s $^{-1}$  (Heida et al. 2017) and a distance estimate of  $9 \pm 4$  kpc for the system. GX 339–4 was observed on three epochs (Table 1) using the LBA during the hard states of three different outbursts (Homan & Belloni 2005; Buxton et al. 2013; Yan et al. 2014) spanning over four years. We observed at a frequency of 8.4 GHz in all three epochs for maximum sensitivity.

#### 3.2 GRS 1716–249

GRS 1716–249 (Nova Oph 1993) was discovered (Ballet et al. 1993) as an X-ray transient in Ophiuchus in 1993. della Valle, Mirabel & Rodriguez (1994) conducted a photometric and spectroscopic analysis of GRS 1716–249 and concluded that the source is at a distance of  $2.4 \pm 0.4$  kpc. The mass of the primary in the system is  $>4.9 M_\odot$  (Masetti et al. 1996). The systemic radial velocity of this system is not yet known. After a prolonged quiescent period (Negoro et al. 2016) following some renewed activity in 1995 (Karitskaya & Goranskij 1995), the source went into outburst again in 2016 December, but did not reach a soft state. The source was observed at three epochs under the LBA program V447 (Tables 1 and 2), and the observations were spaced a few months apart. The last two observations were taken right after the source finished brief softening periods (Bassi et al. 2019). Ceduna did not have valid data for three hours of observations for the first epoch. The last epoch was obtained during a scheduled VLBI run and hence had access to all telescopes in the LBA other than Hartebeesthoek.

#### 3.3 *Swift* J1753.5–0127

*Swift* J1753.5–0127 is a high Galactic latitude system which was first discovered when it went into outburst in 2005 (Palmer et al. 2005). It has one of the shortest known orbital periods ( $3.2443 \pm 0.001$  h) for a BHXB (Zurita et al. 2008). This system remained in outburst for 11 yr before it ultimately faded to quiescence in 2016 November (Russell et al. 2015). The distance to this source is not well known; the best available estimation being 4–8 kpc (Cadolle Bel et al. 2007). The mass of the BH in this system is  $> 7.4 M_\odot$  (Shaw et al. 2016).

*Swift* J1753.5–0127 was observed using the EVN, the VLBA, and the HSA (High Sensitivity Array) for a total of nine epochs. The four VLBA observations in 2009 December were conducted with the dual 13/4-cm recording mode (2.3 and 8.4 GHz), but we only use the 8.4 GHz data to measure the position due to reduced scattering, reduced ionospheric effects that could give rise to systematic errors in astrometry, and higher sensitivity (Table 1). In addition to the standard calibration steps, a global model of the phase calibrator was made by stacking the calibrated data sets of the phase calibrator from all four epochs to prevent minor differences in the model (due to varying uv-coverage) from introducing astrometric systematics. The calibrated data sets of the target from 2008 were also stacked, as the array does not have the capability to detect a week’s motion of the system. *Swift* J1753.5–0127 was detected in the stacked image with a significance of  $\sim 5.2\sigma$ . GBT was a part of the HSA in addition to the standard VLBA dishes for the 8.4 GHz observations in 2010 March, where the target was strongly detected ( $\sim 124\sigma$ ).

The EVN observations of *Swift* J1753.5–0127 were taken as part of a parallax measurement campaign (EM101) in 2012–2013, and consisted of five epochs taken over a period of one year. The phase calibrator J1743–0350, which was used in the earlier VLBA

**Table 2.** Information about the calibrators used. The RA and Dec. positions of the calibrators are those mentioned in the Astrogéo VLBI calibrator search website <http://astrogéo.org/calib/search.html> (rfc2019a catalogue). The integrated flux density is the average of the cleaned flux of all epochs of the calibrator.  $\theta_{\text{sep}}$  is the angular separation of the target from the calibrator. <sup>a</sup>Murphy et al. (2010); <sup>b</sup>Condon et al. (1998); <sup>c</sup>Johnston et al. (1995)

Target	Array	Calibrators	RA (J2000) (h m s)	Dec. (J2000) (° ′ ″)	$\theta_{\text{sep}}$ °	Integrated flux density (Jy)
GX 339–4	LBA	J1711–5028 <sup>a</sup>	17 <sup>h</sup> 11 <sup>m</sup> 40 <sup>s</sup> .9927	−50°28′17″.409	2.21	0.08

observations, was suitable for measuring the proper motion of the target but not the parallax, due to its large angular separation ( $3.36^\circ$ ) from the target. We therefore conducted an X-ray binary calibrator survey on the VLBA (program code BS206) to find closer compact calibrators. We used the multiphase centre capability of the DIFX software correlator (Deller et al. 2011) to correlate on the positions of all NVSS sources within 30 arcmin of the target, observing at 1.6 GHz to give a field of view such that only four pointings were required to cover the desired sky area. Within 30 arcmin of *Swift* J1753.5–0127 we detected two potential calibrators, J1752–0147 (17<sup>h</sup>52<sup>m</sup>18<sup>s</sup>.364, −01°47′16″.685) and J1753–0102 (17<sup>h</sup>53<sup>m</sup>10<sup>s</sup>.4488, −01°02′48″.854). While the latter turned out to be a widely separated double, the former was a compact, single source of peak flux density 6–9 mJy, and was therefore adopted as a secondary phase calibrator for our EVN parallax campaign, and was 0.44° away from our target.

To make sure that we were using the same source models to solve for the delays and rates, we concatenated the calibrated data sets of the primary calibrator for all epochs. This model was then used to derive (epoch-wise) the phase, delay, and rate solutions that were interpolated to the secondary calibrator and the target. The secondary calibrator was then imaged and the data were stacked to obtain a global model (as done by Miller-Jones et al. 2018). The

global model was again used to derive epoch-wise phase solutions that were applied to the target data, which were then imaged. The target positions were then measured by fitting a point source model in the image plane.

## 4 RESULTS – PROPER MOTION MEASUREMENTS

Our VLBI data were used to find the proper motions of GX 339–4 and GRS 1716–249 for the first time. We also measured the proper motion of *Swift* J1753.5–0127, for which *Gaia* also had made a measurement. The position measurements of the three sources at all epochs are summarized in Table 3.

### 4.1 GX 339–4

As shown in Fig. 1, for GX 339–4 a linear fit for the proper motion of the system gives:

$$\begin{aligned}\mu_\alpha \cos \delta &= -3.95 \pm 0.07 \text{ mas yr}^{-1} \\ \mu_\delta &= -4.71 \pm 0.06 \text{ mas yr}^{-1}.\end{aligned}\quad (1)$$

This gives an overall proper motion for GX 339–4 of  $6.15 \pm 0.06 \text{ mas yr}^{-1}$ .

**Table 3.** Summary of the detections of GX 339–4, GRS 1716–249, and *Swift* J1753.5–0127. MJD is taken as the middle of the observing run and the error on MJD is calculated as half the length of the observation. The positions, peak intensities, and errors on each parameter are calculated by fitting an elliptical Gaussian to the target in the image plane.

Target	Project code	MJD (UTC)	RA (J2000) (h m s)	Dec. (J2000) (° ′ ″)	Peak intensity ( $\mu\text{Jy bm}^{-1}$ )
GX 339–4	V430A	$55654.84 \pm 0.25$	$17^{\text{h}}02^{\text{m}}49^{\text{s}}.38260 \pm 0.00004$	$-48^{\circ}47'23''.1413 \pm 0.0003$	$197 \pm 18$
	V486B	$56520.21 \pm 0.24$	$17^{\text{h}}02^{\text{m}}49^{\text{s}}.38164 \pm 0.00001$	$-48^{\circ}47'23''.1534 \pm 0.0001$	$2280 \pm 163$

	EM101E	$56629.75 \pm 0.10$	$17^{\text{h}}53^{\text{m}}28^{\text{s}}.29082 \pm 0.00004$	$-01^{\circ}27'06''.3054 \pm 0.0006$	$109 \pm 21$

**Figure 1.** Proper motion fit for GX 339–4. GX 339–4 was tracked for three epochs over three different outbursts. Top panel: Offset of measured positions relative to the first epoch in right ascension. Bottom panel: Offset of measured positions in declination relative to the first epoch.

#### 4.2 GRS 1716–249

The measured offsets of GRS 1716–249 in RA and Dec. for our three epochs of LBA observations have been plotted in Fig. 2. Measured declinations in these epochs do not appear to follow a linear trend (top panel of Fig. 2). Choosing different subsets of measurements yield drastically different results. The proper motions of the different fits (considering two epochs at a time) in RA agree with each other within the  $1\sigma$  error limit. On the contrary, the proper motion fits in Dec. vary between  $-41$  and  $-2.5$  mas yr $^{-1}$ . This suggests that the measured position in declination for one out of the three epochs is unreliable.

To ascertain which of the epochs were giving accurate positions, we obtained an archival position measurement of GRS 1716–249 from a near-infrared observation to increase the time baseline. We use the position of GRS 1716–249 as measured from the *K*-band image taken on MJD 49263 during the 1994 outburst (Chaty et al. 2002). We fixed the image astrometry to the *Gaia* DR2 frame by cross-matching it with  $\sim 140$  sources from the *Gaia* DR2 catalogue using PYRAF. The proper motions of these sources as reported by *Gaia* DR2 were used to correct the positions of the sources. The position of GRS 1716–249 was determined with an uncertainty of

**Figure 2.** Proper motion fits for GRS 1716–249. GRS 1716–249 was tracked for three epochs over one outburst using the LBA, with positions shown with respect to the first LBA epoch. Top panel: fits by considering position measurements of two epochs at a time in RA and Dec. – epoch 1 and 2 (dashed line); epoch 2 and 3 (dotted line); epoch 1 and 3 (dot-dashed line). The three declination measurements do not lie on a straight line. Lower panel: fitting for proper motion by increasing the time baseline using the 1994 *K*-band image position measurement (dotted line), which breaks the degeneracy and shows that the epoch 1 LBA position is in error (blue and green dashed lines). This was then removed from the fit.

**Figure 3.** Proper motion fit for *Swift* J1753.5–0127. *Swift* J1753.5–0127 was observed for 10 epochs spanning four years. The four observations in 2009 December were concatenated into one position measurement (MJD 55181 to MJD 55190). Top panel: offset of measured positions in right ascension of *Swift* J1753.5–0127 as a function of MJD relative to the first epoch. Bottom panel: offset of measured positions in declination of *Swift* J1753.5–0127 as a function of MJD relative to the first epoch.

~0.2 arcsec. This shows that the position from the first LBA epoch is the cause of the discrepancy. As mentioned in Section 2.2, Ceduna was not available for observing during most of that observing run. Thus the uv coverage was sparse and could explain the wrong position measurement. To determine the true proper motion, we therefore fit using the last two LBA epochs (V447E and V447F) and the position measurement from the 1994 *K*-band image. We obtain the following proper motion

$$\begin{aligned}\mu_{\alpha} \cos \delta &= -3.83 \pm 1.25 \text{ mas yr}^{-1} \\ \mu_{\delta} &= -2.64 \pm 0.75 \text{ mas yr}^{-1}.\end{aligned}\quad (2)$$

This gives an overall proper motion of  $4.65 \pm 1.12 \text{ mas yr}^{-1}$  for GRS 1716–249.

### 4.3 *Swift* J1753.5–0127

Fig. 3 shows a linear fit to the measured positions of *Swift* J1753.5–0127 over a span of four years. Although we used a different calibration scheme for the VLBA and EVN epochs, the nearby secondary calibrator used for the EVN (J1752–0147) was observed using the VLBA primary calibrator J1743–0350 as a phase reference source, such that the two data sets should be referenced to the same absolute reference frame. The absolute astrometric systematics should therefore be of order 0.09 and 0.27 mas, respectively, in RA and Dec. The fit gives a proper motion of

$$\begin{aligned}\mu_{\alpha} \cos \delta &= 0.84 \pm 0.06 \text{ mas yr}^{-1} \\ \mu_{\delta} &= -3.64 \pm 0.06 \text{ mas yr}^{-1}.\end{aligned}\quad (3)$$

This gives a net proper motion of  $3.73 \pm 0.06 \text{ mas yr}^{-1}$ . The proper motion determined above agrees within  $2\sigma$  error limits with that reported by *Gaia* DR2, which is

$$\begin{aligned}\mu_{\alpha} \cos \delta &= 1.13 \pm 0.16 \text{ mas yr}^{-1} \\ \mu_{\delta} &= -3.53 \pm 0.15 \text{ mas yr}^{-1}.\end{aligned}\quad (4)$$

## 5 DISTANCE AND RADIAL VELOCITY ESTIMATES

We will fold the proper motions measured by our VLBI data for the three systems as reported in Section 4, and those available in archival data (using VLBI and *Gaia*) with distance and systemic radial velocities of these systems to get their PKV distribution.

### 5.1 Distance – Milky way prior

The distances to some of the sources in our sample have been inferred from a parallax measurement made by *Gaia* DR2 (Gaia Collaboration 2018) or VLBI. Every *Gaia* measurement of a parallax has an uncertainty associated with it. The fractional errors associated with these measurements are significant, even if they are small in absolute value. Thus, it is essential that these errors are properly considered when converting parallax to distance. In order to make sure that the errors from the measured quantity are appropriately propagated to the inferred quantity, we use a Bayesian inference approach (Astraatmadja & Bailer-Jones 2016).

We use the likelihood function as described in Bailer-Jones (2015) and Gandhi et al. (2019). We follow the work by Grimm, Gilfanov & Sunyaev (2002, GR02 hereafter) to make an analytical model of the LMXB density distribution in our Galaxy to use as the prior. This considers the density of the bulge, disc, and spheroid of the Galaxy, as described by the following equations (equations 4, 5, 6 in GR02).

$$\begin{aligned}\rho_{\text{bulge}} &= \rho_{0,\text{bulge}} \left( \frac{\sqrt{r^2 + \frac{z^2}{q^2}}}{r_0} \right)^{-\gamma} \exp \left( -\frac{r^2 + \frac{z^2}{q^2}}{r_t^2} \right), \\ \rho_{\text{disc}} &= \rho_{0,\text{disc}} \exp \left( -\frac{r_m}{r_d} - \frac{r}{r_d} - \frac{|z|}{r_z} \right), \\ \rho_{\text{sphere}} &= \rho_{0,\text{sphere}} \frac{\exp \left( -b \left( \frac{R}{R_e} \right)^{\frac{1}{4}} \right)}{\left( \frac{R}{R_e} \right)^{\frac{7}{8}}}.\end{aligned}\quad (5)$$

Here  $r$  is the distance from the Galactic Centre of the projected position of the source on the Galactic plane,  $z$  is the height of the source above the Galactic plane, and  $R$  is the distance of the source from the Galactic Centre.  $q$ ,  $r_0$ ,  $r_t$ ,  $r_d$ ,  $r_m$ ,  $r_z$ , and  $R_e$  are scale parameters. GR02 derived these scale parameters for LMXBs by constructing the X-ray luminosity function of these systems. We use the values of these constants as summarized in Table 4 of GR02.  $\rho_{0,\text{bulge}}$ ,  $\rho_{0,\text{disc}}$ , and  $\rho_{0,\text{sphere}}$  are normalization constants. We estimate the density constants  $\rho_{0,\text{bulge}}$ ,  $\rho_{0,\text{disc}}$ , and  $\rho_{0,\text{sphere}}$  for LMXBs using the disc:bulge:sphere mass ratio of 2:1:0.5 as derived by GR02, and assuming the mass of the bulge as  $1.3 \times 10^{10} M_{\odot}$  (GR02). This gave the values of  $\rho_{0,\text{bulge}}$ ,  $\rho_{0,\text{disc}}$ , and  $\rho_{0,\text{sphere}}$  as 1.1, 2.6, and  $13.1 M_{\odot} \text{ pc}^{-3}$ , respectively. We note that the spatial distribution model of GR02 is not exclusively for BHXBs as their work considered neutron star X-ray binaries (NS XRBs) as well, but GR02 is currently the best available model for the spatial distribution of X-ray binaries as existing stellar spatial distributions do not account for kicks.

The parallaxes measured by *Gaia* DR2 have a global zero-point offset of  $-0.029 \text{ mas}$  (Luri et al. 2018). Hence the parallax values from *Gaia* were corrected before being used for the distance estimation using the Milky Way prior. These corrected parallax values along with the estimated values of distances of 11 BHXBs

**Table 4.** PKV distributions for systems that have a systemic radial velocity measurement ( $\gamma$ ) in the literature. The measured quantities are the various parameters for the BHXB systems that were available in the literature, and the estimated quantities are the values that have been determined in this work using the MC simulations code described in Section.  $d_{\text{lit}}$  is the best distance estimate available in the literature for some of these systems. The *Gaia* offset-corrected parallax measurement (as described in Section 5.1) and the distance distribution ( $d_{\text{post}}$ ) estimated using the LMXB Milky way density prior are reported. The 5th and 95th percentiles of these distributions are the upper and lower limits on the distance estimated using the Milky Way prior. For distances in the literature that were just a range, a uniform distribution was used as the input to the MC code. For the distances in literature that have been reported with error bars, the input to our MC code was a Gaussian distribution. The PKV is reported as the median of the PKV probability distribution with the lower and upper limits representing the 5th and 95th percentiles. PKV<sub>post</sub> and PKV<sub>lit</sub> are the PKV distributions using the  $d_{\text{post}}$  and the  $d_{\text{lit}}$  as input distance distributions, respectively. The last column is the suggested birth pathway for the BH in each system and could be supernova (SN), direct collapse (DC), or unsure (U). Refer to Sections 7.1 and 7.4 for the explanation of the suggested birth pathway.

for which *Gaia* DR2 measured parallaxes has been reported in Tables 4 and 5. There are also reports that the *Gaia* DR2 parallaxes on average have a systematic offset of  $-0.075 \pm 0.029$  mas (Xu et al. 2019), but we use the more established  $-0.029$  mas offset (Luri et al. 2018) for the correction of the parallaxes. 11 of the 16 systems in our sample also have distance estimations in the literature (see Tables 4 and 5 for more details), and *Gaia* DR2 measured the parallax of six of those systems (1A 0620–00, XTE J1118+480, GS 1124–684, GRO J1655–40, *Swift* J1753.5–0127, and SAX J1819–2525). We compare the distance estimates derived from *Gaia* parallaxes to the ones available in the literature and use the better constrained distance for determining and analysing the PKV distributions.

## 5.2 Systemic radial velocity estimates

We have four systems with poorly constrained systemic radial velocities (*Swift* J1753.5–0127, MAXI J1820+070, VLA J2130+12, and GRS 1716–249). Using the best distance estimates for these systems, we project them on to the Galactic plane. We estimate the expected systemic radial velocity ( $\bar{\gamma}$ ) of the system at this projected distance on to the Galactic plane and assuming that the system is undergoing pure Galactic rotation about the Galactic Centre. We note that this estimated value of systemic radial velocity is not a true indicator of the systemic radial velocity of the system as it might have received kicks, and thus is probably not following a pure Galactic rotation about the Galactic Centre. Thus for each

**Table 5.** PKV distributions for systems that do not have a systemic radial velocity measurement ( $\gamma$ ) in the literature. For these systems, we calculated the predicted systemic radial velocity ( $\bar{\gamma}$ ) for pure Galactic rotation at a projected distance on the Galactic plane (see Section 5.2 for more details). We run the MC simulations code for five possible systemic radial velocity distributions. The measured quantities are the various parameters for the BHXB systems that were available in the literature, and the estimated quantities are the values that have been determined in this work using the MC simulations code described in Section 6.  $d_{\text{lit}}$  is the best distance estimate available in the literature for some of these systems. The *Gaia* offset-corrected parallax measurement (as described in Section 5.1) and the distance distribution ( $d_{\text{post}}$ ) estimated using the LMXB Milky Way density prior are reported. The 5th and 95th percentiles of these distributions are the upper and lower limits on the distance estimated using the Milky Way prior. For distances in the literature that were just a range, a uniform distribution was used as the input to the MC code. For the distances in literature that have been reported with error bars, the input to our MC code was a Gaussian distribution. The PKV is reported as the median of the PKV probability distribution with the lower and upper limits representing the 5th and 95th percentiles. PKV<sub>post</sub> and PKV<sub>lit</sub> are the PKV distributions using the  $d_{\text{post}}$  and the  $d_{\text{lit}}$  as input distance distributions, respectively. The last column is the suggested birth pathway for the BH in each system and could be supernova (SN), direct collapse (DC), or unsure (U). We have stated that just for the central predicted systemic radial velocity. Refer to Sections 7.1 and 7.4 for the explanation of the suggested birth pathway.

system, we estimate five probable systemic radial velocity Gaussian distributions with medians of  $\bar{\gamma}$ ,  $\bar{\gamma} \pm 50$ , and  $\bar{\gamma} \pm 100$  km s<sup>-1</sup> (see Table 5). We limit our assumed distributions of the systemic radial velocities based on the fact that out of the systems for which systemic radial velocity is measured, the values lie between  $-142 \pm 1.5$  km s<sup>-1</sup> for GRO J1655–40 (Shahbaz et al. 1999) and  $107 \pm 2.9$  km s<sup>-1</sup> for SAX J1819.3–2525 (Orosz et al. 2001).

## 6 ANALYSIS – POTENTIAL KICK VELOCITY

As explained in Section 1.3, peculiar velocity of a system when it crosses the Galactic plane is a better probe to understand the kick a BHXB received when the BH was born. Since all the parameters, namely proper motion, systemic radial velocity, and parallax (or distance), have error bars associated with them, it is crucial to propagate these errors appropriately to estimate the Galactocentric orbits of the systems. The age of most BHXBs is not known, which makes integrating the Galactocentric orbits back to the time of birth

of the BH uncertain. We thus developed an MC methodology that accounts for the errors on the measured quantities and determines the peculiar velocity every time the system crosses the Galactic plane.

The code integrates the Galactocentric orbit of every system in our sample back for 10 Gyr and records the velocity of the system at every plane crossing. Instead of a delta function for the measurement, it involves using Gaussian distributions of the measured parameters with reported uncertainties as standard deviation. Random values are picked from these Gaussian distributions as inputs to *galpy* (Bovy 2014) to create instances of Galactocentric orbits for  $\sim 5000$  random draws to make sure we have sampled the input distribution properly. We assume a Galactic potential given by the *galpy* model MWPotential2014 (see Bovy 2014). The Galactocentric orbits are integrated back in time for 10 Gyr, which exceeds the likely ages of LMXB systems. GRO J1655–40 (Shahbaz 2003), GS 1354–64 (Casares et al. 2009), and SAX J1819–2525 (MacDonald et al. 2014) are intermediate-mass systems and may have a shorter

lifetime than standard LMXBs. Cyg X–1 is an HMXB and has not lived long enough to cross the Galactic plane (Wong et al. 2012). So this calculation, while indicative of the kick, does not represent the system’s true history. To check if the integration of the systems back for 10 Gyr is valid for these systems, we integrated the orbits of these systems back in time for 1 Gyr with 50 000 random draws and found that our results were not affected and were the same as those using 5000 draws and 10 Gyr orbits. Thus, for uniformity we have used a time integration of 10 Gyr for all systems.

The peculiar velocity at each Galactic plane crossing (i.e.  $z = 0$ , where  $z$  is the height above the Galactic plane) is calculated as

$$v_{\text{peculiar}} = [(U - U_0)^2 + (V - V_0)^2 + (W - W_0)^2]^{0.5}. \quad (6)$$

Here  $U$ ,  $V$ , and  $W$  are Galactic space velocities towards the Galactic Centre, in the direction of Galactic rotation, and towards the North Galactic Pole, respectively (Johnson & Soderblom 1987).  $U_0$ ,  $V_0$ , and  $W_0$  are the  $U$ ,  $V$ ,  $W$  components of the Galactocentric space velocities of the local standard of rest at a time when the system crosses the Galactic plane.

This approach allows us to estimate PKV distributions even if all the parameters required to construct the three-dimensional motion are not accurately known. This will also help in estimating the potential kick velocities for newly discovered BHXBs that go into outburst, and when uncertain parameters of known systems are updated with new measurements. The code detailing the MC simulation methodology for estimating the PKV probability distribution and the distance estimation using our Milky way prior is available at the github link <https://github.com/pikkyatri/BHnatalkicks>.

## 6.1 Potential kick velocity distributions of the new VLBI sources

We estimated the PKV probability distributions for the three sources for which we made proper motion measurements: GX 339–4, *Swift* J1753.5–0127, and GRS 1716–249. The proper motion input for the MC simulation is a Gaussian distribution based on the measured proper motion and error bars.

### 6.1.1 GX 339–4

*Gaia* could not make a parallax measurement for GX 339–4. For the distance input we used a uniform distribution between 5 and 13 kpc as estimated by Heida et al. (2017). The system velocity input for the code was a Gaussian distribution based on the measurement of Heida et al. (2017) (Table 4). Running MC simulations for these distributions gives a PKV probability distribution as shown in Fig. 4 with a median of  $200 \text{ km s}^{-1}$  and the 5th percentile at  $122 \text{ km s}^{-1}$ .

### 6.1.2 GRS 1716–249

della Valle et al. (1994) estimated the distance to GRS 1716–249 as  $2.4 \pm 0.4 \text{ kpc}$ , which we used as a Gaussian input prior. The systemic radial velocity of this system has not been measured yet. A system at the Galactocentric radius of GRS 1716–249 and in the Galactic plane is expected to have a systemic radial velocity  $\bar{\gamma}$  of  $\sim -10 \text{ km s}^{-1}$ . We thus run the MC simulations assuming five different Gaussian systemic radial velocity distributions with means of  $-110$ ,  $-60$ ,  $-10$ ,  $40$ , and  $90 \text{ km s}^{-1}$ , all with a  $1\sigma$  of  $50 \text{ km s}^{-1}$ . All five PKV probability distributions have a median above  $\sim 70 \text{ km s}^{-1}$  (see Fig. 5, left-hand panel and Table 4). In

**Figure 4.** PKV probability distribution of GX 339–4 with a median of  $200 \text{ km s}^{-1}$  (dashed line) and a 5th and 95th percentile of  $122$  and  $258 \text{ km s}^{-1}$  (in dotted lines), respectively.

Fig. 5 (right-hand panel) we plotted 20 orbits for the maximum ( $100^{+68}_{-47} \text{ km s}^{-1}$ ) and minimum ( $67^{+41}_{-27} \text{ km s}^{-1}$ ) PKVs corresponding to systemic radial velocities of  $90$  and  $-10 \text{ km s}^{-1}$ , respectively. The orbits stay within the vertical thick stellar disc limits of  $\sim 1 \text{ kpc}$  (Gilmore & Reid 1983).

### 6.1.3 Swift J1753.5–0127

*Gaia* DR2 measured a parallax of  $-0.01 \pm 0.13 \text{ mas}$  for this system. As there is a zero-point offset in all *Gaia* parallax measurements of  $-0.029 \text{ mas}$  (Luri et al. 2018), we use the corrected parallax of  $0.02 \pm 0.13 \text{ mas}$  for our simulations. We determined a posterior distribution for the distance as shown in Fig. 6, left-hand panel. Comparing this with the distance estimated for this source in the literature ( $6 \pm 2 \text{ kpc}$ ) (Cadolle Bel et al. 2007) suggests that the poorly constrained *Gaia* parallax may be overestimating the distance. We thus use a Gaussian distance distribution centred at  $6 \text{ kpc}$  with a  $1\sigma$  of  $2 \text{ kpc}$  as input for the simulations rather than the distance distribution derived using *Gaia* parallax. Along with the distance distribution, we use Gaussian distributions of the proper motion and five different Gaussian distributions (see Section 5.2 and Table 5) as systemic radial velocity ( $\gamma$ ) inputs to calculate the PKV probability distribution (Fig. 6, right-hand panel). Even the lowest median amongst the five PKV probability distributions is at  $142 \text{ km s}^{-1}$ , with the 5th and 95th percentiles as  $76$  and  $243 \text{ km s}^{-1}$ , respectively (see Table 4). Over the past 10 Gyr, the system has reached as high as  $1.5 \text{ kpc}$  above the Galactic plane.

## 6.2 PKV distributions of *Gaia* DR2 and archival sources

We used our methodology (see Section 5.1) to invert the *Gaia* DR2 parallaxes for nine systems that *Gaia* DR2 measured parallaxes, and for two sources (V404 Cyg and VLA J2130+12) that had archival parallax measurements. We have summarized the results for these simulations in Table 4. Out of these 11 systems, seven also had distance constraints in the literature. We used the distance estimations from the literature ( $d_{\text{lit}}$ ) as inputs for the MC simulations to obtain another set of PKV probability distributions for these seven systems (1A 0620–00, GS 1124–684, GRO J1655–40, *Swift* J1753.5–0127, SAX J1819–2525, XTE J1118+480, and MAXI J1820+070). We thus obtain two PKV probability distributions each

**Figure 5.** Left-hand panel: PKV probability distribution of GRS 1716–249 using Gaussian systemic radial velocity ( $\bar{\gamma}$ ) distributions with means of  $-110$ ,  $-60$ ,  $-10$ ,  $40$ , and  $90 \text{ km s}^{-1}$  all with a  $1\sigma$  of  $50 \text{ km s}^{-1}$ . The medians of all the PKV distributions are the blue dashed vertical lines. The lowest PKV probability distribution median is of  $\sim 70 \text{ km s}^{-1}$  and corresponds to the systemic radial velocity of  $-10 \pm 50 \text{ km s}^{-1}$ . Right-hand panel: a 3D visualization of the Galactocentric orbit of GRS 1716–249, integrated for 1 Gyr for 20 orbit instances each of the lowest ( $67^{+41}_{-27} \text{ km s}^{-1}$ ) and highest ( $100^{+68}_{-47} \text{ km s}^{-1}$ ) PKV corresponding to systemic radial velocities of  $-10 \pm 50$  and  $90 \pm 50 \text{ km s}^{-1}$ , respectively. All three axes are in kpc. The system does not go beyond 1 kpc above the Galactic plane in both the cases.

**Figure 6.** Left-hand panel: Posterior distribution function for the distance to *Swift* J1753.5–0127, constructed from the *Gaia* DR2 parallax measurement using the Milky Way LMXB distribution prior (see Section 5.1 for details). The mode of the distribution is at 7.7 kpc. The 5th, 50th, and 95th percentiles of the distance are at 4.8, 8.8, and 20.8 kpc, respectively. Right-hand panel: PKV probability distribution of *Swift* J1753.5–0127 using Gaussian systemic radial velocity ( $\bar{\gamma}$ ) distributions with means of  $-7$ ,  $43$ ,  $93$ ,  $143$ , and  $193 \text{ km s}^{-1}$  all with a  $1\sigma$  of  $50 \text{ km s}^{-1}$ . The input distance distribution of  $6 \pm 2 \text{ kpc}$  was used instead of the distance posterior distribution derived using the *Gaia* parallax as the former was more tightly constrained. The lowest median amongst all the PKV probability distributions is at  $142 \text{ km s}^{-1}$  and the 5th percentiles of all the PKV probability distributions are above  $70 \text{ km s}^{-1}$ .

for these seven systems, but use the PKV probability distributions determined using the literature distance estimates ( $d_{\text{lit}}$ ) for further analysis of these systems as they were more tightly constrained.

We used the distance posterior derived from parallax measurements for our PKV probability distributions for four systems, namely GS 1354–64, Cyg X–1, V404 Cyg, and VLA J2130+12, as they did not have better distance estimates in the literature (See Tables 4 and 5). We tested the sensitivity of the PKV distribution of these four systems to the prior we are using to calculate the distance posterior, using an exponentially decreasing volume density prior (Astraatmadja & Bailer-Jones 2016; Gandhi et al. 2019) to determine a revised PKV distribution. The only system showing a marked difference in the PKV distributions from the two priors was GS 1354–64, with a revised median PKV of

$183^{+102}_{-64} \text{ km s}^{-1}$  as compared to  $213^{+88}_{-78} \text{ km s}^{-1}$  from the Milky Way prior. However, even this difference was within the uncertainties of the PKV distribution using the Milky Way prior.

For V404 Cyg, we use the archival VLBI proper motion and parallax measurements (Miller-Jones et al. 2009a) as they were more precise than the *Gaia* DR2 measurements. The parallax and proper motion for VLA J2130+12 were measured by Kirsten et al. (2014), though there is no available estimate of its systemic radial velocity. We thus used the expected radial velocity of a source at the Galactocentric distance of VLA J2130+12 but in the Galactic plane as the input for estimating its PKV probability distribution. For systems that did not have measured parallaxes, we use the best estimates on distance present in the literature (Table 5). *Gaia* DR2 did not measure proper motions for MAXI J1836–194 and

GRS 1915+105, so we also use archival VLBI proper motion measurements for these systems. We have reported the 5th, 50th, and 95th percentiles for both the distance distribution that we determined using the LMXB Milky Way prior described in Section 5.1, and for the potential kick velocities for these systems.

MAXI J1820+070 was first detected in 2018 March (Kawamuro et al. 2018) and is still being monitored in the radio and X-ray bands. We obtained an upper limit on the distance of the system as  $3.9 \pm 0.6$  kpc by constraining the proper motions of the receding and approaching jets observed in existing VLA data (Bright et al., in preparation). For a lower limit on the distance, we used the X-ray flux reported by *Swift* at the soft-to-hard X-ray spectral state transition. We assume that the state transition happens between 1% and 4% of the Eddington luminosity (Maccarone 2003; Kalemci et al. 2013) to estimate a distance of 1.7 kpc. We have run our simulations using the distance inferred from the *Gaia* parallax and also using the distance limits as mentioned above. As this distance is better constrained than the *Gaia* DR2 distance, we have used the former for estimating the PKV distribution of MAXI J1820+070.

## 7 DISCUSSION

### 7.1 Potential kick velocity distribution – BHXB population

We investigated the distribution of the potential kick velocities in BHXB systems based on the results in Section 6. Given the probabilistic nature of these results (probability distributions for the predicted velocity of each system), we follow the Bayesian hierarchical methodology outlined by Mandel (2010) and Hogg, Bovy & Lang (2010) for fitting a distribution model. We evaluate the distribution of posteriors with unimodal (with mean of  $\mu$  and standard deviation of  $\sigma$ ) and bimodal (with means of  $\mu_1, \mu_2$ , standard deviations of  $\sigma_1, \sigma_2$ , and weights of  $w_1$  and  $w_2 = 1 - w_1$ ) Gaussian models. For this purpose, we used a Hamiltonian Markov chain Monte Carlo (MCMC) algorithm (Neal 2011; Betancourt 2019) with No U-Turn Sampling (NUTS; Hoffman & Gelman 2011) as implemented in PYMC3 (Salvatier, Wiecki & Fonnesbeck 2016). We assumed uninformative priors for all parameters in the models and verified convergence in the final samples for all parameters using the Gelman–Rubin diagnostic test (Gelman & Rubin 1992), with  $\hat{R} < 1.001$  for all parameters ( $\hat{R}$  closer to one indicates certainty of convergence of the chains).

We evaluated the distribution with both models over two sets of velocities, with one set containing all the BHXB systems in our sample (16 systems), and a second set containing only the systems with systemic radial velocities that have been measured in the literature (12 systems). The results for both models in both cases are tabulated in Table 6 and plotted in Fig. 7.

Due to the low number of ‘events’ (number of systems for which we have kick velocity PDFs), we used the corrected Akaike information criterion (AICc; Akaike 1974; Cavanaugh 1997; Burnham & Anderson 2002) to compare the models. As tabulated in Table 6, the unimodal distribution is clearly favoured in both cases (a smaller AICc suggests a better model). Removal of systems with loose systemic radial velocity constraints provides a marginal relative improvement to the bimodal model, as the difference between the AICc parameter reduced when evaluated for a sample devoid of loose systemic radial velocity constraints as compared to a sample that consisted of all 16 systems. It is worth noting however that the clear separation of posterior constraints for  $\mu_1$  and  $\mu_2$  in the bimodal model (given the uninformative priors) hints at the possibility of a bimodal nature for the distribution of the potential BHXB kicks,

but testing this model is currently hampered by the low number of BHXB systems with PKV constraints.

To demonstrate that neither of the two components in the bimodal model are caused by a single source, we plot all individual distributions in Fig. 8. We find that there are at least four systems (first four systems in Fig. 8) contributing to the lower velocity peak ( $41 \text{ km s}^{-1}$ ), which could be consistent with birth of the BH by direct collapse. We find at least nine systems (SAX J1819–2525 to *Swift* J1753.5–0127 in Fig. 8) clearly contributing to the higher velocity peak ( $136 \text{ km s}^{-1}$ ). Better constraints on some of the measured parameters for systems like GS 1124–684, VLA J2130+12, GS 1352–64, *Swift* J1753.5–0127, and SAX J1819–2525 might help in tightening their PKV probability distributions, which could change the form (and interpretation) of the PKV distribution of BHXB population. With the current available data on BHXBs, our results provide the best constraint we can obtain for the PKV distribution of BHXBs.

### 7.2 Potential kick velocity interpretation

The PKV that we estimate here is not the actual natal kick the BH receives when it is born, but is the potential peculiar velocity of the system, with which it may have been kicked out of the Galactic plane. Calculating the actual BH natal kick from the BHXB peculiar velocity at Galactic plane crossing is complex and depends on modelling the system (Repetto et al. 2012, 2017), taking into account the orbital period, the component masses of the binary system, the direction of the kick, and the mass ejected in the SN explosion (Nelemans et al. 1999). It also involves simulating the subsequent dynamical interaction of the sources and evolution of the binary system. These parameters are currently not well constrained for most systems, and thus simulating the evolution of these systems to determine the actual BH natal kick is out of the scope of this paper. Hence the peculiar velocity of the system at Galactic plane crossing is currently the best proxy that we can use for BH natal kicks in a population-wide analysis such as this one. Since most star-forming regions are in the Galactic plane, it is probable that most BHXBs form in the Galactic plane. Since we do not know the time of BH birth, we instead consider the velocity of the system every time it crosses the Galactic plane as a potential velocity kick the system might have received.

According to Mignard (2000), stellar velocity dispersions due to Galactic interactions are the order of  $\sim 50 \text{ km s}^{-1}$  for old systems (and lower for younger systems). Since BHXBs are more massive than these systems, they will suffer even lower velocity dispersions. Thus we classify systems with potential kick velocities higher than the  $\sim 50 \text{ km s}^{-1}$  limit as systems that might have received strong kicks, and hence the BH in the BHXB might have formed in an SN explosion. We suggest that the systems with a median PKV of less than  $\sim 50 \text{ km s}^{-1}$  are systems with weak potential kicks, and thus could well have formed by direct collapse rather than an SN explosion. Systems that have a PKV distribution such that their median is  $> 50 \text{ km s}^{-1}$  but the 5th is lower than  $50 \text{ km s}^{-1}$  do not clearly fall into either category, and hence we could not deduce their likely birth mechanism. We find two such sources in our sample, namely VLA J2130+12 and GRS 1716–249. 10 systems in our sample are likely to have been formed in an SN explosion, whereas four systems could plausibly have formed by direct collapse. We summarize the results of our analysis in Tables 4 and 5.

The PKV probability distribution of GRS 1915+105 (median  $\sim 49 \text{ km s}^{-1}$ ) suggests that it could have been born via direct collapse, as the PKV is within the velocity dispersion limits for Galactic

**Table 6.** Model estimates for the PKV distribution using unimodal and bimodal Gaussian models when all systems are considered and when only systems with well-constrained radial systemic velocity ( $\gamma$ ) are considered. Reported values are medians ( $\mu$ ) of the posterior distributions, along with uncertainties ( $\sigma$ ) and all values are in  $\text{km s}^{-1}$ .  $w_1$  is the weight of the Gaussian distribution with the mean  $\mu_1$ . AICc is the corrected Akaike information criterion. A smaller AICc suggests that the model is more favourable.

		$\mu_1$	$\sigma_1$	$\mu_2$	$\sigma_2$	$w_1$	AICc
All systems	Unimodal	$107 \pm 16$	$56 \pm 14$	—	—	—	−16.3
	Bimodal	$41 \pm 14$	$19 \pm 10$	$136 \pm 17$	$32 \pm 18$	$0.3 \pm 0.1$	−2.2
Systems with $\gamma$	Unimodal	$112 \pm 22$	$65 \pm 19$	—	—	—	−2.4
	Bimodal	$35 \pm 10$	$11 \pm 9$	$145 \pm 15$	$30 \pm 17$	$0.3 \pm 0.1$	10.7

**Figure 7.** Realizations of the inferred unimodal (top) and bimodal (bottom) distributions for potential kick velocities ( $v$ ), inferred from the data ( $d$ ). The blue lines represent the model corresponding to the median values from the posterior sample for data from all the systems in the sample, while the red dashed lines represent the model based on the median from the posterior sample for data from the 12 systems with systemic radial velocity ( $\gamma$ ) constraints. The faint grey lines are a small random subset from the posterior MCMC sample for all the systems, as a demonstration of uncertainty.

scattering ( $\sim 50 \text{ km s}^{-1}$  for late-type stellar systems; Mignard 2000). According to our results the  $v_{95}$  values for V404 Cyg and 1A 0620–00 are lower than the  $v_{95}$  for GRS 1915+105, suggesting that V404 Cyg and 1A 0620–00 might also have been born without a strong natal kick. The probability of a compact object receiving a kick between angle  $\theta$  and  $\theta + d\theta$  during an SN explosion varies as  $\frac{1}{2} \sin \theta d\theta$ , where  $\theta$  is the angle the kick makes with the direction of the peculiar velocity of the system before the explosion. Thus it is also possible that these low PKV systems were born with an SN explosion but their velocity was reduced due to an asymmetry in the explosion counteracting the recoil kick. For Cyg X–1, the median of the PKV we obtain is in agreement with the estimation of Wong et al. (2012) and suggests a direct collapse birth (albeit with the caveat that this is an HMXB and has never crossed the Galactic plane in its lifetime, so our methodology is not strictly applicable).

For our interpretation of PKV as the BH natal kick, we are assuming that none of the systems in our sample were born in GCs. There have been no confirmed BHXBs in GCs, though there are

**Figure 8.** PKV probability distributions of the 16 BHXBs in our sample. It can be seen that no single system is responsible for either of the two most prominent peaks in the aggregated natal kick distribution.

some candidates (Camilo et al. 2000; Strader et al. 2012; Chomiuk et al. 2013; Miller-Jones et al. 2015). GCs only contain 5–10 per cent of the total number of known Galactic X-Ray binaries (Clark 1975; Bahramian et al. 2014), so this population is likely to be a small fraction of the total BHXBs in the Galaxy.

The Galactocentric orbits in the past 10 Gyr also show that only four (GRO 1655–40, SAX J1819–2525, GX 339–4, and MAXI J1836–194) out of the 16 systems ever get within 2 kpc of the Galactic Centre, which is the truncation radius for a spheroidal bulge model (Dehnen & Binney 1998). We note that we have classified these systems as having an SN birth, but due to their possible association with being bulge objects we cannot rule out the high PKV as being due to bulge formation and/or interactions.

**Figure 9.** Comparison of best-fitting unimodal and bimodal BHXB PKV distributions to the best pulsar kick velocity distribution. The BHXB PKV unimodal distribution is represented by the solid line and has a median of  $107 \text{ km s}^{-1}$ . The BHXB PKV bimodal distribution is represented by the dotted line. The best fit, two Maxwellian model for the peculiar velocities of pulsars (Verbunt et al. 2017) is denoted by the dashed line. The unimodal BHXB PKV distribution median is close to the low kick pulsar kick velocity component. There is a dearth of extremely high PKV BHs corresponding to the high-velocity Maxwellian component for the pulsar velocity distribution.

### 7.3 Comparison with NS natal kicks

The kick velocity distribution of pulsars has been extensively studied (e.g. Fryer, Burrows & Benz 1998; Arzoumanian, Chernoff & Cordes 2002; Hobbs et al. 2005), whereas there is no well-documented kick velocity measurement catalogue for NS XRBs. Thus to understand the relation between NS and BH natal kicks, we compare our BHXB PKV distribution with the pulsar kick velocity distribution (Verbunt et al. 2017). BHXBs and pulsars suffer from different observational biases. The distance to pulsars is usually smaller than the distance to BHXBs, and thus their detection is less affected by extinction. Pulsars just have their two-dimensional velocities measured, there are no systemic velocity measurements for pulsars. Also, it is possible to observe pulsars that might have received strong enough kicks to disrupt the binary they were a part of, whereas our data sample only consists of BHs that are in binaries. Keeping these biases in mind, we compare BHXB and pulsar kick velocities.

Theory suggests that fallback of matter ejected in an SN on to the proto-neutron star can give rise to BHs, so we expect similarities in the kick distributions of BHs and NSs. The most recent NS peculiar velocity distribution is fit better with two Maxwellian components than one (V17). Our bimodal Gaussian (Fig. 9) fit to the data shows that the medians of the two Gaussians in the BHXB PKV distribution ( $41 \pm 14$  and  $136 \pm 17 \text{ km s}^{-1}$ ) are lower than the NS peculiar velocity peaks ( $120$  and  $540 \text{ km s}^{-1}$ ) for the best-fitting model by V17 by a factor of three to four. This may suggest that BHs receive weaker natal kicks as compared to NSs by a factor that is similar to the mass ratios of standard BHs and NSs. This is in contrast to the conclusion of Repetto et al. (2012), where it was shown that BHs and NSs get equally strong kicks. This mismatch of the medians of the two components of the BHXB PKV distribution and pulsar kick velocity distribution could also be because of different kick mechanisms in BHs and NSs. For BHs the low-velocity kick is probably due to formation by direct collapse, whereas low NS kicks have been attributed to various mechanisms

like ultra-stripped SNe (Tauris, Langer & Podsiadlowski 2015), electron capture SNe (Gessner & Janka 2018), and collapse of low iron mass cores (Podsiadlowski et al. 2004).

Our unimodal fit to the BHXB PKV data matches the lower Maxwellian component of the pulsar kick velocity distribution (Fig. 9). However, we are biased against stronger kicks, since they can unbind BHXBs and make them unobservable whereas pulsars can be observed even in an unbound state. Due to this selection bias, we expected the BHXB PKV distribution kicks to be lower than the V17 peculiar velocities.

### 7.4 Supernova mass-loss

We find that there are at least nine systems of the 16 in our sample set that clearly received strong natal kicks ( $> 50 \text{ km s}^{-1}$ ). This makes SN birth more probable for these systems than direct collapse BH birth. We note that our sample set may be biased against observing direct collapse BHs. This is because they will not receive strong kicks and will be located close to the Galactic plane, where detecting distant BHXBs is challenging due to high extinction and scattering.

Symmetric mass-loss ( $\Delta M$ ) during an SN explosion is one of the reasons for a natal kick. However, this mass-loss has to be  $< 0.5(M_{\text{He}} + m)$  for the binary to remain bound (Blaauw 1961), where  $M_{\text{He}}$  is the mass of the progenitor helium star and  $m$  is the mass of the donor star. Thus the maximum possible recoil velocity due to symmetric mass-loss can be estimated by constraining the maximum possible mass ejected in the BHXB system without unbinding the binary. This was given by Nelemans et al. (1999) as

$$v_{\text{sys}} = 213 \left( \frac{\Delta M}{M_{\odot}} \right) \left( \frac{m}{M_{\odot}} \right) \left( \frac{P_{\text{re-circ}}}{d} \right)^{-1/3} \times \left( \frac{(M_{\text{BH}} + m)}{M_{\odot}} \right)^{-5/3} \text{ km s}^{-1}, \quad (7)$$

where  $\Delta M$ ,  $M_{\text{BH}}$ , and  $m$  are the mass ejected in the SN, mass of the BH, and mass of the donor immediately after the SN, respectively.  $P_{\text{re-circ}}$  is the period of the re-circularized orbit of the system after the formation of the BH, and it is assumed that no mass transfer occurs until the re-circularization of the orbit is complete.  $v_{\text{sys}}$  is the recoil kick velocity the system should have received due to the symmetric mass-loss in the SN explosion. Nelemans et al. (1999) estimated the maximum possible recoil kick velocities for GS 1124–684 and GRO 1655–40 and found that they were limited to  $< 40 \text{ km s}^{-1}$ . Our estimated PKV for all these systems is greater than those estimated by Nelemans et al. (1999) in the case of only symmetric mass ejection. We thus suggest that the observed kick velocity of these systems is not only because of symmetric mass-loss in an SN explosion, but due to these systems receiving additional acceleration due to asymmetries associated with the SN explosion (Janka 2017).

Gualandris et al. (2005) suggested that XTE J1118+480 received an asymmetric kick that put the system in its current Galactocentric orbit. We measured a PKV of  $186 \pm 28 \text{ km s}^{-1}$  for XTE J1118+480, which agrees with the peculiar velocity measurement of Gualandris et al. (2005). Systems like 4U 1543–475, GS 1354–64, SAX J1819.3–2525, and MAXI J1820+070 also have high enough PKVs to suggest asymmetries in the SN explosions, keeping in mind that we are assuming that these systems are similar to the ones already studied in the literature (e.g. Nelemans et al. 1999; Gualandris et al. 2005). The observed metal abundances in XTE J1118+480 (González Hernández et al. 2006), GRO J1655–40

(González Hernández et al. 2008), and SAX J1819.3–2525 (Orosz et al. 2001) also point towards contamination of these sources by an SN and support the hypothesis that they were probably born in SN explosions.

### 7.5 Natal kicks and z-distribution

In the past, the distribution of the distance from the Galactic plane ( $\|z\|$ ) has been used to determine the strength of BH natal kicks (e.g. van Paradijs & White 1995; Jonker & Nelemans 2004; Repetto et al. 2017). We plot the median of the current height probability distributions of all BHXBs in our sample using our distance posterior distributions (Table 7) in Fig. 10. It can be seen that all systems with a PKV  $< 100 \text{ km s}^{-1}$  are within 500 pc of the Galactic plane, other than VLA J2130+12. We conducted Pearson and Spearman rank correlation tests to check the correlation of the distance to the Galactic plane ( $\|z\|$ ) with PKVs of BHXBs. We found a potential correlation between the two, with correlation coefficients of  $0.51 \pm 0.15$  ( $p = 0.02$ ) and  $0.56 \pm 0.13$  ( $p = 0.01$ ) for Pearson and Spearman Rank tests, respectively. This, however does not suggest that systems at small heights from the Galactic plane received low kick velocities because of the two outliers GRO J1655–40 and GS 1354–64. This could be because the systems are passing through the plane at the present time, which is the case for GRO J1655–40 as it is on a path towards the Galactic plane in its orbit (Gandhi et al. 2019). The distance estimate of GS 1354–64 is poorly constrained and could be the reason for a misleading current height above the Galactic plane. Thus, the strength of PKV a BHXB receives cannot be determined solely by the current  $\|z\|$ . Hence, the approach that we take is currently the best that can be done to estimate natal kick distributions.

Comparisons between the root-mean-square distance from the Galactic plane ( $z_{\text{rms}}$ ) for BHXBs and NSs have led to contrasting claims about BH natal kicks. NSs and BHs have different observational biases and these contrasting claims could be an artefact of that. White & van Paradijs (1996) suggested that BHs get reduced kicks as compared to NSs. Jonker & Nelemans (2004) updated the distances to these systems and showed that BH natal kicks are as strong as those of NSs. We now update the  $z_{\text{rms}}$  as we have new distances (in some cases better constrained distances) for BHXBs. Our analysis gives the  $z_{\text{rms}}$  of BHXBs as  $\sim 700$  pc, which is higher than those estimated by White & van Paradijs (1996) ( $\sim 410$  pc) and Jonker & Nelemans (2004) ( $\sim 625$  pc), but lower than the most recent estimate by Repetto et al. (2017) ( $\sim 980$  pc). If we exclude the halo object XTE J1118+480, the  $z_{\text{rms}}$  for BHXBs drops down to 595 pc. If we are to believe the relation between  $z_{\text{rms}}$  and BHXB kick distribution, this would then suggest that NSXBs ( $z_{\text{rms}} = 1$  kpc; van Paradijs & White 1995) receive stronger kicks as compared to BHXBs. We arrived at a similar conclusion when we compared pulsar kick velocities with BHXB PKVs in Section 7.3, but with the caveat of the selection bias of our sample of BHXBs. Hence, even though the current  $\|z\|$  of the BHXBs in our data sample is not a strong proxy for the PKV of individual systems,  $z_{\text{rms}}$  is a good way to compare the PKV distributions of our sample of BHXBs to the NSs. This could be because systems spend most of their time close to the orbit extrema, and when we average the current heights of a sample, we remove the bias of the epoch of observation.

### 7.6 Natal kicks and black hole mass

Attempts have been made to understand if there is any relation between BH mass and the natal kick it receives (Mirabel 2017).

This could assist in understanding the correlation between the final pathway a progenitor takes to become a BH and the mass of the BH. The current theoretical understanding does not show a direct correlation and suggests that there is no clean mass cut-off for direct collapse formation (Sukhbold et al. 2016). We have obtained observational constraints on the potential kicks of 16 BHXBs (Fig. 10), which increases the sample size and updates the estimations of BHXB kicks by Mirabel (2017) and Gandhi et al. (2019) (current peculiar velocity used as proxy in both works). We conducted correlation tests, which indicated negligible correlation between BH mass and kick, with a Pearson Rank coefficient of  $-0.23 \pm 0.17$  ( $p = 0.21$ ) and a Spearman Rank coefficient of  $-0.2 \pm 0.17$  ( $p = 0.40$ ). We used a standard mass of  $8 \pm 3 M_{\odot}$  (Kreidberg et al. 2012) for the systems that do not have a dynamically measured mass (see Table 7 for a summary of masses used). Removing these systems from the test sample gave Pearson and Spearman rank coefficients of  $-0.36 \pm 0.16$  ( $p = 0.20$ ) and  $-0.31 \pm 0.17$  ( $p = 0.28$ ), respectively. Using BHXB potential kick velocities as an indicator of BH natal kick, we suggest that there is no significant dependency of BH mass on natal kick. This is the first time there has been observational evidence to support the simulations of Sukhbold et al. (2016), although we stress that the large error bars in the masses of the BHs (e.g. Ziolkowski 2008) are a caveat.

### 7.7 BHs in globular clusters

XTE J1118+480 is argued to be a GC escapee because of its high peculiar velocity and high Galactic latitude. We find at least five systems with PKVs comparable to XTE J1118+480, making this system non-unique. However, most LMXBs are relatively old systems and thus may have come from low-metallicity environments like GCs. So a GC origin of these high PKV systems cannot be ruled out. Since the majority of the systems in our sample get strong kicks, then if this distribution is characteristic of BHs it would imply that the retention fraction may be fairly low in GCs. As GCs are dense stellar environments, they are ideal sites for forming binaries. The escape velocities of GCs are of the order of a few tens of  $\text{km s}^{-1}$  (Gnedin et al. 2002; Belczynski et al. 2006). Thus, most of the BHs should be eventually ejected from the GC due to kicks associated with their birth or dynamical interactions (Kulkarni, Hut & McMillan 1993; Drukier 1996). The recent increase in the number of BHXB candidates detected in GCs challenges this theory (Camilo et al. 2000; Strader et al. 2012; Chomiuk et al. 2013; Miller-Jones et al. 2015; Giesers et al. 2018). Recent simulations have shown that if GCs retain  $\sim 1000$  BHs, then these BHs will produce a considerable population of BHXBs in the GCs (Giesler et al. 2018). Simulations that estimate the BHs retained in GCs use various observationally unconstrained distributions ranging from random flat kick distributions up to some value (Sippel & Hurley 2013) through to unconstrained retention fractions (Giesler et al. 2018). Our PKV distribution shows that these assumptions should be used with caution. The range of assumptions for the kick distributions also emphasize the need for a consistent, observationally constrained distribution.

According to our results the 20th percentile of the PKV distribution for BHXBs is  $\sim 45 \text{ km s}^{-1}$ , which is the typical  $v_{\text{esc}}$  for GCs. This suggests that BHXBs, which could have weaker recoil kicks than isolated BHs due to remaining bound, have a very high probability of getting kicked out from GCs. On the contrary, if BHXBs are Blaauw kick dominated, then isolated BHs have a higher chance of being retained in GCs. Thus, at birth, the retention fraction

**Table 7.** Current  $\|z\|$  and PKV estimates for every source, along with the assumed mass used for the correlation test. The PKV is the median of the PKV probability distribution and the error bar is the  $1\sigma$  deviation of the distribution. Current  $\|z\|$  is the median of the current  $\|z\|$  distribution for the estimated distance distributions for each BHXB and the errors are the  $1\sigma$  of the distributions. GS 1354–64, MAXI J1836–194, GRS 1716–249, MAXI J1820+070, and VLA J2130+12 do not have dynamical mass measurements, so we assumed BH masses of  $8 M_\odot$  (Kreidberg et al. 2012).

**Figure 10.** *Left:* the variation of PKV with the current height of the system above the Galactic plane. There are five systems with a PKV below  $100 \text{ km s}^{-1}$  and within 500 pc of the Galactic plane. There are two systems that are within 500 pc but have PKVs  $>100 \text{ km s}^{-1}$ . *Right:* the variation of PKVs with BH mass. The systems marked with blue squares have had their proper motion measured by VLBI and the systems marked with pink diamonds had their proper motion measured by *Gaia*. The systems marked with yellow circles had their proper motions measured by VLBI, but we used the updated proper motions measured by *Gaia* for our simulations. We have assumed a BH mass of  $8 M_\odot$  to represent the systems that do not have dynamical mass measurements (Kreidberg et al. 2012). The error bars are one standard deviation of the PKV probability distributions. No correlation between BH mass and PKV is seen, even after disregarding the systems without dynamical mass measurements.

of BHs in GCs could be lower than the current estimates and may need to be updated. However, we note that GCs are old systems with low metallicity, and we have no observational constraints on how metallicity might affect the kick distribution.

### 7.8 Implications for BH–BH systems

When a star in the binary undergoes an SN explosion, any asymmetry in the kick could misalign the spin of the remnant BH to the orbital plane. If tidal interactions are then unable to realign the spin, this could potentially give rise to a high degree

of misalignment of the spins of the BH to the orbital plane of the BH–BH binary (Gerosa et al. 2013). Recent observations of the GW merger event GW151226 suggested that natal kicks  $>50 \text{ km s}^{-1}$  were needed to explain the inferred spin–orbit misalignment of the binary (O’Shaughnessy, Gerosa & Wysocki 2017). The spin measurements for three other GW events GW150914, LVT151012, and GW170104 indicated that there is a possibility for these systems to either have low intrinsic spins or large spins that are misaligned with the binary orbit (Farr et al. 2017). 90 per cent of our sources have PKVs higher than  $50 \text{ km s}^{-1}$ , thus suggesting that spin–orbit misalignment might be a common phenomenon.

Based on LIGO’s BH binary merger observations it was suggested that BHs receive high natal kicks  $\sim 200 \text{ km s}^{-1}$  if the tidal processes do not realign stellar spins (Wysocki et al. 2018). If however tidal processes do realign the spins, kicks of the order of  $50 \text{ km s}^{-1}$  are still needed to explain the observations. The bimodality in our natal kick distributions, albeit based on a few sources, could potentially arise from similar tidal effects, though more work needs to be done in order to draw definitive conclusions. Theoretical estimates suggest that the majority of BH binaries that will be observed with the third LIGO run will be part of a population in which the first-born BH is slowly spinning, and support low natal kicks for BHXBs (Bavera et al. 2019; Fuller & Ma 2019). Measuring PKVs for more BHXBs and future LIGO observations will be essential to reconcile these theoretical expectations of low natal kicks with our observational constraints of high PKVs.

### 7.9 BHXB spin–orbit misalignment

Study of X-ray power density spectra of BHXBs show low-frequency quasi-periodic oscillations (QPOs) in the power density spectra of almost all BHXB systems (Ingram et al. 2016). Theoretical models suggest that such QPOs could be a result of Lense–Thirring precession (Stella & Vietri 1998), which is a phenomenon where material out of the BH equatorial plane (e.g. due to misalignment of the BH spin and binary orbit) precesses due to relativistic frame dragging. Any natal kick imparted to a BH at its birth could cause a spin–orbit misalignment in the remnant BHXB. Since realignment time-scales of BHXBs are usually longer than the ages of these systems (Martin, Reis & Pringle 2008), realignment of the BH spin to the orbital plane is not likely to be common (unless the donor star in the BHXB was initially an intermediate-mass donor; Fragos & McClintock 2015). We found that a majority of the BHXBs in our sample set were strongly kicked, which is consistent with the prevalence of low-frequency QPOs and provides strong evidence for spin–orbit misalignment in BHXBs.

Extensive efforts to measure the spins of BHs in BHXBs have been made in the past decade. The best available methods (McClintock, Narayan & Steiner 2014; García et al. 2018) often assume that the spin of the BH is aligned with the orbital plane of the binary. Our finding that strong natal kicks are imparted to  $\sim 85$  per cent of BHXBs suggests that caution may be warranted in assuming the binary orbital inclination when fitting for BH spin.

## 8 CONCLUSIONS

In this paper, we report on measurements of proper motions of three BHXB systems using VLBI. We collated the proper motions, systemic radial velocities, and distances of 16 BHXB systems. We developed a methodology to determine PKV distributions for BHXB systems. We also developed an MC simulation code to account for uncertainties in the measured proper motions, systemic radial velocities, and distances when determining the PKV that the BHXB received, providing robust observational constraints on the possible kick velocities of these systems. We estimated PKV probability distributions for 16 BHXBs and found that  $\sim 75$  per cent of our sample has a median PKV of  $> 70 \text{ km s}^{-1}$ , which we interpreted as a majority of BHXBs acquiring strong kicks when they are born. We combined the PKV probability distributions for these 16 BHXBs to obtain an aggregate PKV distribution. We found that a unimodal Gaussian distribution with a mean of  $107 \pm 16 \text{ km s}^{-1}$  fit the data better than a bimodal distribution, which is potentially consistent with the LIGO’s BH–BH merger observations and natal

kick estimations. Alternatively, the fit suffers from low number of systems in the data sample and hence we could not rule out a bimodal distribution. We found no significant correlation between PKVs and BH mass. We did not find any strict mass cut-off for BHs to form with an SN or by direct collapse.

We conducted Spearman and Pearson rank correlation tests to determine the correlation between the current height above the Galactic plane of a BHXB and the PKV it received. We found that even though there is a potential correlation between the two (coefficient of  $\sim 0.5$  for both tests), we should avoid using  $|z|$  as a natal kick proxy. We compared our aggregated PKV distribution with the pulsar peculiar velocity distribution (Verbunt et al. 2017) and found that BHs may get weaker kicks than NSs by a factor of three to four. Our finding that BHXB kick velocities are greater than typical escape velocities of GCs favours a large fraction of BHs being kicked out of GCs. The prevalence of strong kicks in our BHXB sample is in agreement with the ubiquity of low-frequency QPOs and hence spin–orbit misalignment in almost all BHXBs.

## ACKNOWLEDGEMENTS

We would like to thank Poshak Gandhi for his useful inputs on the low-mass X-ray binary prior to be used for our Bayesian Inference Analysis. PYRAF is a product of the Space Telescope Science Institute, which is operated by AURA for NASA. The Long Baseline Array is part of the Australia Telescope National Facility which is funded by the Australian Government for operation as a National Facility managed by CSIRO. We would like to thank the Institute of Radio Astronomy and Space Research, AUT University, New Zealand for the use and operational support of their radio telescopes in the collection of data for this work. This work used the Swinburne University of Technology software correlator, developed as part of the Australian Major National Research Facilities Programme. The Australian SKA Pathfinder is part of the Australia Telescope National Facility which is managed by CSIRO. Operation of ASKAP is funded by the Australian Government with support from the National Collaborative Research Infrastructure Strategy. ASKAP uses the resources of the Pawsey Supercomputing Centre. Establishment of ASKAP, the Murchison Radio-astronomy Observatory, and the Pawsey Supercomputing Centre are initiatives of the Australian Government, with support from the Government of Western Australia and the Science and Industry Endowment Fund. We acknowledge the Wajarri Yamatji people as the traditional owners of the Observatory site. The European VLBI Network (EVN) is a joint facility of independent European, African, Asian, and North American radio astronomy institutes. Scientific results from data presented in this publication are derived from the following EVN project code(s): EM101. The Long Baseline Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. The GBT is part of the Green Bank Observatory, a facility of the National Science Foundation operated under a cooperative agreement by Associated Universities, Inc. This work has used data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement. JCAM-J is the recipient of an Australian Research Council Future

Fellowship (FT140101082) funded by the Australian government. PGJ acknowledges funding from the European Research Council under ERC Consolidator Grant agreement number 647208. MAPT acknowledge support by the Spanish Ministry of Economy, Industry and Competitiveness (MINECO) under grant AYA2017-83216-P and support via a Ramón y Cajal Fellowship (RYC-2015-17854). SC acknowledges funding from CNES (french space agency), through MINE, the Multi-wavelength INTEGRAL Network.
